ABSTRACT
This experiment was aimed to investigate the Toxicopathological effect of N, N-Dimethylformamide (DMF) (1/10LD50) on the adult male rats' liver. Sixteen adult male rats were used in this experiment. After acclimatization for two weeks, they were divided equally into two groups as follows: Group-C: Control: Normal diet and water for 30 days (n=8 rats). Group-T1: DMF 645.5mg/kg. B.W as 1/10LD50 for 30 days (n=8 rats), after thirty days collected blood for liver enzymes analysis then all animals killed at the end of the experiment and the liver samples saved at 10% formalin for histopathological preparation. The results showed that serum liver enzymes (ALP, ALT, and AST) concentrations of adult male rats after thirty days of oral DMF administration were significantly different (P<0.05) from the control group. Histopathological changes of group 1/10 LD50 (T1) group appear enlargement of hepatocytes with mild degeneration and mild hyperplasia of kupffer cells, and focal infiltration of inflammatory cells mainly lymphocytes in the portal area and a large area of necrosis.

Keywords: dimethylformamide, hepatotoxicity, liver enzyme, serum, kupffer.

INTRODUCTION
Dimethylformamide (DMF) a major solvent predominantly used in the chemical industry and is a colorless to slightly yellow liquid with a faint amine-like odor. DMF has low volatility and can be miscible with water and the majority of organic liquids, and thus is globally used in a wide variety of industrial applications (12, 27). DMF is mainly used in the production of inorganic chemicals, synthesized organic materials, pesticides, and leather, fabrics, plastics, and polyurethane materials (3). Also DMF used in pharmaceutical products (23). DMF is released into the environment as it enters various areas of the industry, affecting air quality as well as the health of humans and animals. China consumes the most DMF and produces roughly 45% of the world's DMF each year. China consumes two-thirds of the world's DMF (27). As the use of DMF has increased year after year, so has concern about its potentially toxic effects. DMF has been shown in animal experiments and epidemiological studies to be toxic to the liver, kidneys, and reproductive system in both humans and animals (7). Previous research has found that the severity of DMF-induced liver injury is directly related to exposure dosage, time of exposure, and the patient's liver function individuals exposed (17). Therefore, the toxicity of an industrial solvent could also differ depending on the experimental animals' species, age, strain, sex and route of administration (24). There have been previous reports of workers developing hepatic dysfunction as a result of DMF alone or in combination with other organic solvents (11). Hepatitis, fibrosis, cirrhosis, and cancer are among the liver toxicities caused by DMF (12). Because there have been few studies on DMF in Iraq, we designed this study to look into its potential toxicity in rats.

MATERIALS AND METHODS
Experimental design
Sixteen adult male rats were used in this experiment. After acclimatization for two weeks they were divided equally into two groups, First group control (C): Eight rats were orally distilled water daily for Thirty days. And the second group (T1): Eight rats were received oral dose 1/10LD50 of DMF daily for thirty days.

Chemical
All chemicals purchase from (Alpha Chemika) India.

Preparation of DMF dose
The LD50 of DMF was estimation in rats using the Up and down method (1, 2).

Experiment animals
Sixteen male Albino rats weighing 300-350 gm were used in the experiment. They ranged in age from 10 to 12 weeks. Animals were obtained from the University of Baghdad College of Veterinary Medicine - animal house, acclimatized to laboratory conditions, and housed in plastic cages for two weeks at ambient temperatures of 25°C and 45-55 % relative humidity, with 12 hours of dark and light. Distilled water was used to treat the animals, according to Laboratory Animal Care Principles. To maintain a clean environment, bedding is changed every five days (5).

Blood collection
Blood samples were collected through cardiac puncture using disposable medical syringes (5 ml) at thirty days. The blood samples of each rat were stored in disposable tubes that were kept for no more than four hours before serum insulation. Samples were centrifuged for 15 minutes at a speed of 3000 rpm and then serum samples were placed in the freezer at -18 °C before biochemical tests (18).

Biochemical Analysis
Activities of some enzymes and concentrations of certain biochemical parameters representing liver functions were determined in the rats blood as follows: Aspartate aminotransferase (AST), alanine aminotransferase (ALT), and Alkaline Phosphatase (ALP) activities were determined according to the method (15).

Histopathological Changes
Histological samples were taken from the animals after killing, and the liver was preserved in 10% formalin as a fixative to prepare histopathological sections after the thirty days from oral administration of DMF. The paraffin sections it thickness 3 - 4 μm were prepared and stained with hematoxylin and eosin (H and E) for histopathological examination under light microscopy (26).

Statistical analysis : Data of time recovery were analyzed as one way-ANOVA using the
RESULTS AND DISCUSSION

Data in Table 1 shows that serum liver enzymes (ALP, ALT, and AST) concentrations of adult male rats after thirty days of oral DMF administration were increased significantly different (P< 0.05) from the control group. After the thirty days, the results showed that the concentration of ALP, ALT and AST in the treated group was significantly higher than in the control group (Table 1).

Histopathology results

Histopathological changes of group 1/10LD$_{50}$ (T1) group (Fig-1) showed enlargement of hepatocytes with mild degeneration and mild hyperplasia of kupffer cells, while focal infiltration of inflammatory cells mainly lymphocytes in the portal area and a large area of necrosis consist of MNCs mainly lymphocytes and there is RBCs also revealed respectively (Fig-2,3). Fig-4 shows a multifocal area of centrilobular necrosis. Mild degenerative change of hepatocytes, with focal aggregation of inflammatory cells around a congested blood vessel notes (Fig-5).

Figure 3. Histopathological section of liver of T1 group shows large area of necrosis consist of MNCs mainly lymphocytes and there is RBCs also (Blue arrow) (H&E stain 400X).
DMF is a toxic metabolite that is liberated in the liver after CYP2E1 metabolizes various endogenous and exogenous substrates to reactive metabolites, resulting in reactive oxygen species (ROS) (25). Several studies have shown that DMF can cause liver toxicity, which is characterized by an increase in the activities of serum liver enzymes such as AST, ALT, and ALP (6). DMF-induced liver damage was also demonstrated by an increase in serum enzymes. ALT, AST, and ALP are three important types of liver enzymes that are commonly used to assess hepatocyte damage. In the previous study, administration of DMF at concentrations of 0.32 g/kg, 0.63 g/kg, and 1.26 g/kg for 90 days resulted in increased serum levels of ALT, AST, and ALP, indicating that DMF caused the liver injury (19). In a previous study it was shown that, after exposure to DMF, it leads to the production of reactive oxygen species that cause an increase in blood transaminases, such as AST, ALT and ALP which were useful indicators in assessing liver injury in workers who are professionally exposed to DMF (10). And histological changes such as necrosis and fibrosis (19). DMF is metabolized by cytochrome P4502E1 to monomethyl and formamide derivatives like as N-hydroxymethyl-N-methylformamide (HMMF) (21). HMMF degrades thermolytic to form formaldehyde and N-methyl formamide (NMF). Because NMF is a potent hepatotoxicant in rodents, it is thought that this transformation is responsible for DMF's liver-damaging properties (16). In mice exposed to 1.26 g / kg DMF for 90 days, central hepatocyte enlargement of the liver exhibited massive hepatic swelling and perinuclear vacuoles with mild cell degeneration and fibrosis, as well as inflammatory cell infiltration (19). An increase in the observed was observed in rats upon exposure centrilobular hepatocellular hypertrophy to DMF (14). At 50 mg/kg B.W. per day for 90-day dietary, mild effects on the liver (enlargement of hepatic cells) (9). The liver was the primary site of toxicity in rats and mice exposed to inhaled DMF for 13 weeks. Centrilobular hepatocellular necrosis seen in exposed rats was accompanied by increased activities of hepatic intracellular enzymes in the serum, and also by increases in relative liver weights. The centrilobular hepatocellular hypertrophy seen in exposed mice was accompanied by increased absolute and relative liver weights (13). DMF-induced death in rats was induced by significant centrilobular necrosis of the liver associated with hemorrhage and congestion for rats exposed to DMF from 2-wk to 13-wk at concentrations of 100-200-400-800 ppm for inhalation (22) Other studies have revealed that high exposure to DMF is responsible for biochemical and histopathological changes in the liver, including necrosis and disintegration of hepatocytes, as a result of oxidative stress caused by free radical production (10). DMF-
induced liver damage may reflect disturbance in liver cell metabolism, which results in distinctive changes in serum enzyme levels (4). Because they are cytoplasmic and are released into the circulation after cellular damage, ALT, AST, and ALP are the most sensitive signifiers used in the diagnostic test of hepatic damage (20).

CONCLUSIONS
Exposure to dimethylformamide should be considered one factor caused hepatitis and enhanced activities of hepatic enzymes in the circulation of injured liver by DMF of rats.
